Abstract

We dissolve the quantum measurement problem within Recognition Science (RS). The problem—how and when does the wave function collapse?—arises from treating measurement as an external process applied to a quantum system. In RS, measurement *is* recognition: the discrete ledger commits to a definite outcome at each 8-tick epoch boundary. The ledger has two phases: *uncommitted* (superposition of branches with complex amplitudes) and *committed* (single definite outcome). The transition is the irreversible ledger commit operation—this is "collapse." The Born rule $P(i) = |c_i|^2$ follows from five constraints: non-negativity, normalization, J-cost phase invariance, additivity under coarse-graining, and continuity. We show that $P(i) = |c_i|^2$ is the unique probability assignment satisfying all five. Definite outcomes are forced by the discreteness of the ledger (one entry per tick). The 8-tick epoch ($2^D = 8$ for $D = 3$) provides the minimal complete measurement cycle. Schrödinger's cat, Wigner's friend, and the quantum-to-classical transition are all resolved by the same mechanism.

1 Introduction

The measurement problem, identified by von Neumann in 1932 [3], remains the central interpretive puzzle of quantum mechanics. Every interpretation must answer three questions:

1. **When** does the wave function collapse?
2. **How** does a superposition become a definite outcome?
3. **Why** is the probability rule $P = |\psi|^2$?

The standard formalism [4] contains two evolution laws: unitary Schrödinger evolution (deterministic, reversible, linear) and projection (stochastic, irreversible, nonlinear). No mechanism specifies when one law replaces the other.

Proposed solutions include:

- **Copenhagen**: Collapse occurs upon "observation" (undefined).
- **Many-Worlds** [5]: No collapse; all branches exist.
- **Bohmian mechanics** [6]: Deterministic particles guided by ψ; collapse is epistemic.
- **GRW** [7]: Spontaneous collapse at random times.

- **QBism** [8]: ψ encodes agent beliefs.

Recognition Science [2] does not *solve* the measurement problem within the existing framework; it *dissolves* it by providing a framework in which the problem does not arise.

2 The Cost Functional

Definition 2.1 (RS Cost Functional)**.** For $x > 0$:

$$J(x) = \tfrac{1}{2}(x + x^{-1}) - 1. \tag{1}$$

The functional J is the unique continuous solution to three axioms:
Axiom A1 (Normalization): $J(1) = 0$.
Axiom A2 (Recognition Composition Law, RCL): $J(xy) + J(x/y) = 2J(x)J(y) + 2J(x) + 2J(y)$ for all $x, y > 0$.
Axiom A3 (Calibration): $J''_{\log}(0) = 1$, where $J_{\log}(t) := J(e^t)$.

Theorem 2.2 (Cost Uniqueness)**.** *The unique continuous solution to* (A1)–(A3) *is* $J(x) = \frac{1}{2}(x + x^{-1}) - 1$.

Proof sketch. Setting $f(t) = J_{\log}(t) + 1$ and rewriting (A2) gives the d'Alembert equation $f(s + t) + f(s - t) = 2f(s)f(t)$. By the Aczél classification theorem [1], the unique continuous solution with $f(0) = 1$ and $f''(0) = 1$ is $f(t) = \cosh t$. □

Lemma 2.3 (Phase Invariance)**.** *J depends only on the modulus: for $z = r\,e^{i\theta}$ with $r > 0$,*

$$J(|z|) = J(r) \quad \textit{(independent of } \theta\textit{)}. \tag{2}$$

3 The Ledger Commit Model

Definition 3.1 (Uncommitted Ledger State)**.** An uncommitted ledger state is a superposition of branches:

$$|\Psi\rangle = \sum_i c_i\,|b_i\rangle, \quad c_i \in \mathbb{C}, \quad \sum_i |c_i|^2 = 1, \tag{3}$$

where $|b_i\rangle$ are orthogonal branch states with complex amplitudes c_i.

Definition 3.2 (Committed Ledger State)**.** A committed ledger state is a single definite outcome $|b_k\rangle$. All bond multipliers take integer values—no superposition.

Definition 3.3 (Collapse = Commit)**.** The transition uncommitted $\to$ committed is the ledger commit operation. At every 8-tick epoch boundary ($t \bmod 8 = 0$), the ledger commits to one branch $|b_k\rangle$ with probability $P(k)$ determined by the amplitudes $\{c_i\}$. What $P(k)$ is—and the fact that it equals $|c_k|^2$—follows from the uniqueness theorem in Section 4; it is not part of this definition.

Proposition 3.4 (Measurement Irreversibility — Structural Argument)**.** *The commit operation is irreversible: a committed ledger entry cannot be uncommitted.*

Proof. The ledger's double-entry bookkeeping records every commit as a balanced transaction (debit and credit). Reversing a commit would require creating an unbalanced entry (credit without debit). An unbalanced entry violates the Recognition Composition Law, giving $J \to \infty$. Therefore, the commit is permanent. □

Remark 3.5. Irreversibility resolves the puzzle of "von Neumann's Process 1 vs. Process 2." Unitary evolution (Process 2) is the inter-tick dynamics of the uncommitted ledger. The commit (Process 1) occurs at epoch boundaries. Both are part of the same physical system; they operate at different phases of the 8-tick cycle.

4 The Born Rule Derived

Theorem 4.1 (Born Rule from J-Cost)**.** *Let $P : \mathbb{C}^n \to [0,1]^n$ assign probabilities to the branches of an uncommitted ledger state $|\Psi\rangle = \sum_i c_i|b_i\rangle$. Suppose P satisfies:*

(i) ***Non-negativity****: $P(i) \geq 0$ for all i.*
(ii) ***Normalization****: $\sum_i P(i) = 1$.*
(iii) ***Phase invariance****: $P(i)$ depends on c_i only through $|c_i|$ (J is phase-independent, Lemma 2.3).*
(iv) ***Additivity****: P respects coarse-graining: grouping k equal-amplitude branches into one outcome gives probability $k \cdot P(\text{single branch})$.*
(v) ***Continuity****: $P(i)$ is continuous in $|c_i|$.*

Then $P(i) = |c_i|^2$.

Proof. By (iii), $P(i) = f(|c_i|)$ for some function $f : [0,\infty) \to [0,1]$.

Step 1 (equal amplitudes). Consider a state with n equal-amplitude branches: $c_i = e^{i\theta_i}/\sqrt{n}$. By (iii), all $P(i)$ are equal. By (ii), $nf(1/\sqrt{n}) = 1$, so $f(1/\sqrt{n}) = 1/n = (1/\sqrt{n})^2$.

Step 2 (coarse-graining). Take n branches of equal amplitude $1/\sqrt{n}$. Group the first k branches into a single coarse-grained outcome. By additivity, the probability of the coarse-grained outcome is $kf(1/\sqrt{n}) = k/n$. By relabeling, this is also $f(\sqrt{k/n})$ (since the coarse-grained amplitude is $\sqrt{k/n}$). Therefore $f(\sqrt{k/n}) = k/n = (\sqrt{k/n})^2$ for all integers $0 \leq k \leq n$.

Step 3 (density and continuity). The set $\{\sqrt{k/n} : k, n \in \mathbb{N},\ 0 \leq k \leq n\}$ is dense in $[0,1]$ (since $\{k/n\}$ is the set of rationals and $\sqrt{\cdot}$ preserves density). By condition (v) (continuity), f agrees with r^2 on a dense set and is continuous, so $f(r) = r^2$ for all $r \in [0,1]$. Therefore $P(i) = |c_i|^2$. □

Remark 4.2 (Interference from the Born Rule). For a two-branch superposition $|\Psi\rangle = c_1|b_1\rangle + c_2|b_2\rangle$, the Born rule gives the probability of measuring the superposed amplitude $c_1 + c_2$ as:

$$|c_1 + c_2|^2 = |c_1|^2 + |c_2|^2 + 2\,\mathrm{Re}(c_1^*\, c_2). \tag{4}$$

The cross-term $2\,\mathrm{Re}(c_1^*\, c_2)$ is the interference term, responsible for quantum interference phenomena. In the ledger, this cross-term represents the cost of maintaining phase coherence between two branches; it vanishes upon decoherence (commit).

Proposition 4.3 (Post-Measurement Definiteness)**.** *After the commit, the ledger state is definite: $P(\text{outcome}) = 1$. No further branching occurs until the next 8-tick epoch.*

Structural argument. By Definition [Committed Ledger State], a committed state is a single branch $|b_k\rangle$. The probability assigned to $|b_k\rangle$ by the Born rule (Theorem 4.1) is $|1|^2 = 1$. The definition of "commit" includes the commitment holding until the next 8-tick epoch boundary; there is no second commit within the same epoch. □

5 Definite Outcomes from Discreteness

Proposition 5.1 (No Superposition of Committed Entries)**.** *Each committed ledger entry is a single definite integer-valued record. Superposition describes the uncommitted inter-tick phase only.*

Proof. The ledger is discrete: each cell contains exactly one integer-valued entry. An entry cannot be in a superposition of values, just as a database record cannot be "half 0 and half 1." The discreteness forces a definite outcome at every commit. □

Remark 5.2. This is the RS answer to "How does a superposition become a definite outcome?" The answer: the superposition was never "real" in the ontic sense. It describes the inter-tick dynamics of an uncommitted state. The committed state—the physically real record—is always definite.

6 The 8-Tick Measurement Cycle

Proposition 6.1 (Complete Measurement Cycle)**.** *One complete measurement cycle is one 8-tick epoch ($2^D = 8$ ticks for $D = 3$).*

Proof. The D-cube has $2^D = 8$ vertices. The phase structure traverses $e^{2\pi ik/8}$ for $k = 0, 1, \ldots, 7$. At the half-period ($k = 4$): $e^{i\pi} = -1$, generating the complex structure. At the full period ($k = 8$): $e^{2\pi i} = 1$, restoring real values. The commit occurs at this boundary, when the phase cycle returns to $+1$. □

Corollary 6.2. *The measurement timescale is $\tau_{\text{meas}} = 8\tau_0$, where τ_0 is the fundamental tick time. At macroscopic scales, this is negligibly short.*

7 Schrödinger's Cat Dissolved

Proposition 7.1 (No Macroscopic Superpositions)**.** *Schrödinger's cat is never in a superposition of alive and dead. The radioactive decay event commits at a specific 8-tick boundary, and the cat's state follows deterministically from that commit.*

Proof. The radioactive nucleus has an uncommitted state during each 8-tick epoch. At the epoch boundary, the ledger commits: either "decayed" or "not decayed." This commit propagates causally through the apparatus to the cat within subsequent ticks. At no point does the macroscopic system enter a superposition. The apparent superposition in the standard formalism arises from extending unitary evolution past the commit boundary—a domain error in the semiclassical approximation. □

8 Wigner's Friend Resolved

Proposition 8.1 (Wigner's Friend)**.** *The Wigner's friend paradox does not arise in RS. Both Wigner and his friend observe the same committed ledger entry.*

Proof. The friend performs a measurement (commit) at epoch boundary t_1. The result is recorded in the ledger as a definite entry. When Wigner later queries the friend, he reads the same committed entry. There is no "superposition of the friend's knowledge":

the ledger is a shared, objective record. Wigner's ignorance of the result before querying is epistemic, not ontic. □

Remark 8.2 (Extended Wigner's Friend). The same mechanism resolves the extended Wigner's friend scenario of Frauchiger and Renner [11]. Their paradox arises when two observers reason about each other's quantum measurements and arrive at contradictory conclusions. In RS, the ledger provides a single observer-independent record: all observers read the same committed entries, and no contradiction arises.

9 The Quantum-to-Classical Transition

Proposition 9.1 (Decoherence from J-Cost Scaling — Order-of-Magnitude Argument)**.** *Macroscopic superpositions decohere on timescales vastly shorter than any observable timescale, because the J-cost of maintaining entanglement scales as N^2 with particle number.*

Structural argument (order of magnitude). Consider a system of N particles. A *product state* has total J-cost $J_{\text{prod}} \sim N$ (sum of N independent terms of order 1). A fully *entangled state* (all N entries correlated) incurs off-diagonal correlation costs from all $\binom{N}{2} \sim N^2/2$ pairs, giving $J_{\text{ent}} \sim N^2$. The cost differential $\Delta J = J_{\text{ent}} - J_{\text{prod}} \sim N(N-1)$ drives decoherence: the system minimizes J-cost by transitioning from entangled to product states at a rate proportional to ΔJ. For $N \sim 10^{23}$ (macroscopic), $\Delta J \sim 10^{46}$, and decoherence is effectively instantaneous. □

Remark 9.2 (Status of the N^2 scaling). The J-cost $\sim N^2$ scaling for the entangled state counts the $\binom{N}{2}$ pairwise correlation terms. This is a *structural estimate*; a rigorous derivation of the decoherence rate from the full RS Hamiltonian (with precise coupling constants) is an identified open problem. The parametric argument correctly captures the essential physics: entanglement maintenance becomes increasingly costly at large N, providing a natural J-cost-based explanation of the quantum-to-classical transition without a Heisenberg cut.

Remark 9.3. This explains why quantum effects are observable at microscopic scales ($N \sim 1$, $\Delta J \sim 0$) but not at macroscopic scales ($N \gg 1$, $\Delta J \gg 1$). The transition is smooth, not sharp—there is no "Heisenberg cut."

10 Comparison with Interpretations

	Copen.	**MWI**	**Bohm**	**GRW**	**RS**
Collapse	Observer	None	Epistemic	Random	Commit
ψ status	Epistemic	Ontic	Ontic	Ontic	Inter-tick
Born rule	Postulated	Derived*	Equivariant	Derived	Derived
Definite	Observer	All occur	Particles	Stochastic	Discrete
Evolution reversible	Yes	Yes	Yes	No	No
Free params	0	0	0	2	0

*MWI derivations of the Born rule remain contested [9, 10].

11 Predictions and Falsifiers

1. **No macroscopic superpositions**: Detection of a macroscopic superposition persisting beyond $8\tau_0/N$ (where N is the particle count) would challenge the commit model.

2. **Born rule exact**: Any violation of $P = |\psi|^2$ at any scale would falsify the J-cost derivation.

3. **Measurement time**: The minimum measurement duration is $8\tau_0$. If measurements could be completed in fewer than 8 ticks, the epoch structure would be falsified.

4. **Irreversibility**: The commit is irreversible. Any demonstration of "uncollapse"—reversing a definite measurement outcome to a superposition—would falsify RS.

5. **No Heisenberg cut**: The quantum-to-classical transition is smooth (governed by N^2 scaling), not sharp. Discovery of a sharp boundary would challenge the J-cost decoherence mechanism.

12 Conclusion

The measurement problem is dissolved: recognition *is* measurement. The ledger commits to definite outcomes at each 8-tick epoch boundary. The Born rule is the unique probability assignment satisfying five structural constraints: non-negativity, normalization, J-cost phase invariance, additivity under coarse-graining, and continuity. Definite outcomes are forced by ledger discreteness. Collapse is the irreversible commit operation. Schrödinger's cat is never in a superposition. Wigner's friend reads the same ledger. The quantum-to-classical transition is governed by J-cost scaling (N^2 vs. N). No observer, no many worlds, no pilot wave, no spontaneous collapse—just the ledger.
