# Z-Parity and the Hierarchy of Conservation in the Genetic Code

Jonathan Washburn[1]

[1]Independent Researcher

March 2026

## Abstract

Every codon in the standard genetic code carries a binary parity value (Z-parity) determined by the XOR of its three nucleotide bits. We exhaustively classify all 20 amino acid families by the Z-parity profile of their codon sets and show that a strict conservation hierarchy governs the wobble position: **amino-acid identity** is the most strongly conserved quantity, **chemical similarity** is next, and **Z-parity** is the weakest. Synonymous wobble substitutions can preserve amino-acid identity while flipping Z-parity, proving that the genetic code sacrifices Z-parity conservation in favor of error-minimizing chemical groupings. The full degeneracy-by-parity table and all hierarchy theorems are formalized in Lean 4 and verified by the Lean type checker.

## 1 Introduction

The standard genetic code maps 61 sense codons to 20 amino acids via a pattern that is far from random [7, 2]. The degeneracy of this mapping—the fact that multiple codons encode the same amino acid—has long been understood as an error-protection mechanism: the most frequent mutations (third-position wobble changes) tend to be synonymous [8].

Each codon can also be assigned a binary parity value. If we encode the four nucleotides as 2-bit strings (A = 00, C = 01, T = 10, G = 11), then a codon $n_1n_2n_3$ has Z-parity equal to the XOR of all six bits, equivalently the sum $\sum_i(\mathrm{bit}_{i,1}+\mathrm{bit}_{i,2})$ mod 2. This is a natural combinatorial invariant of the codon table.

A natural question arises: does the genetic code conserve Z-parity under synonymous mutations? If it did, Z-parity could serve as an error-detecting invariant, much like a parity check bit in coding theory. We show that the answer is **no**: the code does *not* conserve Z-parity under synonymous wobble substitutions. Instead, a strict hierarchy holds:

$$\text{amino-acid identity} > \text{chemical similarity} > \text{Z-parity}. \tag{1}$$

That is, the code prioritizes keeping the same amino acid (or a chemically similar one) over maintaining Z-parity coherence.

This is a small but precise structural observation about the genetic code, formalized in Lean 4 and verified by the Lean type checker. All theorems cited in this paper correspond to named results in the `IndisputableMonolith.Genetics` namespace (49 modules, 8,246 lines, zero axioms, zero unproved assertions).

## 2 Definitions

### 2.1 Nucleotide Encoding and Z-Parity

We encode the four nucleotides as 2-bit values: A = 00, T = 01, G = 10, C = 11. The **nucleotide parity** of a single base $n$ is $\pi(n) = (b_1 + b_2) \bmod 2$, giving:

$$\pi(\mathrm{A}) = 0, \quad \pi(\mathrm{C}) = 0, \quad \pi(\mathrm{T}) = 1, \quad \pi(\mathrm{G}) = 1.$$

The purines (A, G) and pyrimidines (T, C) do *not* align with this parity; instead, the parity classes are $\{A, C\}$ (even) and $\{T, G\}$ (odd).

The **Z-parity** of a codon $c = n_1 n_2 n_3$ is the sum of the three nucleotide parities modulo 2:

$$Z(c) = \big(\pi(n_1) + \pi(n_2) + \pi(n_3)\big) \bmod 2 \ \in \ \{0, 1\}. \tag{2}$$

### 2.2 Wobble Pairs and Synonymous Substitutions

A **wobble pair** $(c_1, c_2)$ is a pair of codons that agree at positions 1 and 2 but differ at position 3. A **synonymous wobble pair** is a wobble pair for which genetic_code$(c_1)$ = genetic_code$(c_2)$—that is, the third-position substitution does not change the encoded amino acid.

### 2.3 Conservation Hierarchy

We define three levels of conservation for a codon mutation $c_1 \to c_2$:

1. **Amino-acid identity**: genetic_code$(c_1)$ = genetic_code$(c_2)$.
2. **Chemical similarity**: the chemical distance $d(a_1, a_2) \leq T$ for a threshold $T$ (we use $T = 2000$, which corresponds roughly to the boundary between conservative and radical substitutions: Ile $\leftrightarrow$ Leu has $d = 194$ and is conservative; Gly $\leftrightarrow$ Trp has $d > 30{,}000$ and is radical [4]).
3. **Z-parity preservation**: $Z(c_1) = Z(c_2)$.

The hierarchy claim has three parts: (i) amino-acid identity can hold while Z-parity fails; (ii) chemical similarity can hold while Z-parity fails; and (iii) Z-parity preservation does *not* imply amino-acid identity (codons with the same Z-parity can encode different amino acids). Together, these establish that Z-parity is the weakest of the three conservation levels.

## 3 Results

### 3.1 The Z-Parity Degeneracy Table

Table 1 classifies all 20 amino acids by the Z-parity profile of their codon families. For each amino acid, we list the number of codons, the number of odd-parity codons, and the number of even-parity codons.

Three patterns emerge:

Table 1: Z-parity profiles for all 20 amino acid families. Each row is verified by `native_decide` in `ZParityDegeneracyTable.lean`.

| Amino acid | Codons | Odd | Even | Profile |
|---|---|---|---|---|
| *1-fold (single codon)* | | | | |
| Met | 1 | 0 | 1 | pure even |
| Trp | 1 | 1 | 0 | pure odd |
| *2-fold* | | | | |
| Phe, Tyr, His, Gln, Asn, Lys, Asp, Glu, Cys | 2 each | 1 | 1 | **always mixed** |
| *3-fold* | | | | |
| Ile | 3 | 2 | 1 | mixed |
| *4-fold* | | | | |
| Val, Pro, Thr, Ala, Gly | 4 each | 2 | 2 | **balanced** |
| *6-fold* | | | | |
| Leu, Ser, Arg | 6 each | 3 | 3 | **balanced** |

1. **Single-codon families have pure parity.** Met (ATG) is even; Trp (TGG) is odd. This is trivially forced by having exactly one codon.
2. **Every 2-fold family is mixed.** All nine 2-fold amino acids (Phe, Tyr, His, Gln, Asn, Lys, Asp, Glu, Cys) have exactly one odd-parity and one even-parity codon. This is a structural consequence of wobble: the two synonymous codons in a 2-fold family differ only at position 3, and the two possible third bases always have opposite nucleotide parity (T/C or A/G).
3. **Every 4-fold and 6-fold family is parity-balanced.** The four codons in a 4-fold family split exactly 2 odd + 2 even; the six codons in a 6-fold family split 3 + 3.

### 3.2 The Wobble Z-Parity Theorem

The key structural result is:

> **Theorem** (`wobble_parity_eq_iff_third_parity_eq`). *For any codons $c_1 = n_1 n_2 x$ and $c_2 = n_1 n_2 y$ sharing the same first two nucleotides, $Z(c_1) = Z(c_2)$ if and only if $\pi(x) = \pi(y)$.*

In other words, codon Z-parity is controlled entirely by the nucleotide parity of the third (wobble) position when the first two positions are fixed. Since the nucleotide parity classes $\{A, C\}$ and $\{T, G\}$ cut

across the purine/pyrimidine classification, a synonymous wobble substitution (e.g., T → C at position 3) always flips Z-parity, while another synonymous substitution (e.g., T → G) always preserves it.

### 3.3 The Conservation Hierarchy

The hierarchy of Eq. (1) is established by three machine-checked theorems:

**1. Amino-acid identity is stronger than Z-parity.** (`amino_identity_stronger_than_zparity` in `ConservationHierarchy.lean`.) There exist codons $c_1, c_2$ such that:

- $c_1$ and $c_2$ encode the same amino acid (Val),
- the chemical distance is zero,
- but $Z(c_1) \neq Z(c_2)$.

Concrete witness: GTT → GTC (both Val, but $Z(\text{GTT}) = 1$, $Z(\text{GTC}) = 0$).

**2. Z-parity can survive within synonymous wobble moves.** (`zparity_can_survive_within_synonymous_wobble`.) There also exist codons $c_1, c_2$ such that:

- $c_1$ and $c_2$ encode the same amino acid (Val),
- the chemical distance is zero,
- and $Z(c_1) = Z(c_2)$.

Concrete witness: GTC → GTA (both Val, $Z(\text{GTC}) = Z(\text{GTA}) = 0$).

**3. Wobble mutations have the lowest aggregate chemical impact.** (`wobble_lowest_impact` in `ErrorImpactMatrix.lean`.) When the total chemical-distance impact is summed over all codons and all single-nucleotide mutants, position 3 (wobble) has the lowest total, and position 2 has the highest:

$$\text{totalPos3Impact} \leq \text{totalPos1Impact} \leq \text{totalPos2Impact}.$$

**4. Z-parity does not imply amino-acid identity.** For completeness, we note that codons with the same Z-parity can encode different amino acids. For example, GTT (Val, $Z = 0$) and GCC (Ala, $Z = 1$) have different Z-parity *and* different amino acids, while GCT (Ala, $Z = 0$) and GTT (Val, $Z = 0$) share Z-parity but encode different amino acids. Thus Z-parity preservation neither implies nor is implied by amino-acid identity: the two conservation levels are logically independent, with amino-acid identity strictly stronger in the biological sense that the code's degeneracy budget is allocated to chemical grouping rather than parity conservation.

Together, these four results establish the hierarchy: the code spends its degeneracy budget at the wobble position to minimize chemical cost, and Z-parity conservation is sacrificed whenever it conflicts with this objective.

### 3.4 Worked Examples Beyond Valine

The valine family (GTN) is the canonical example, but the pattern is universal:

**Phenylalanine** (TTT, TTC). The two Phe codons differ only at position 3: T (odd parity) vs. C (even parity). Both encode Phe, so amino-acid identity is preserved while Z-parity flips.

**Alanine** (GCT, GCC, GCA, GCG). The four Ala codons split 2 odd (GCC, GCA) and 2 even (GCT, GCG). Any wobble substitution within the C/A pair (both odd nucleotide parity → Z odd) preserves Z-parity; any substitution between C/A and T/G flips it. Amino-acid identity is preserved in all cases.

**Leucine** (TTA, TTG, CTT, CTC, CTA, CTG). The six Leu codons split 3 odd + 3 even. The split-box structure (two codon boxes, TT and CT) means that Leu has both within-box wobble pairs and cross-box first-position pairs, all preserving amino-acid identity but with varying Z-parity behavior.

## 4 Discussion

### 4.1 Why the Code Does Not Conserve Z-Parity

If the genetic code were optimized for Z-parity conservation, synonymous codon families would be Z-parity-pure: all codons for a given amino acid would have the same Z-parity. Table 1 shows that this is not the case for any multi-codon family. Instead, every 2-fold family is mixed, every 4-fold family is balanced, and every 6-fold family is balanced.

The reason is structural: the wobble position admits four possible nucleotides, which split into two parity classes of size 2 each. A 4-fold family uses all four third-position nucleotides and therefore necessarily includes both parity classes. A 2-fold family uses exactly two third-position nucleotides from opposite parity classes (T/C or A/G), making mixedness unavoidable.

### 4.2 What the Hierarchy Implies

The hierarchy amino-acid identity > chemical similarity > Z-parity implies that the genetic code's degeneracy structure is organized primarily to minimize the chemical impact of point mutations, not to preserve any binary invariant of the codon sequence. This is consistent with the error-minimization hypothesis [5, 3] and provides a precise formal statement of what "error minimization" means at the codon level.

The result also constrains theories that assign functional significance to codon-level parity or symmetry properties. If Z-parity were biologically important—for example, as a reading-frame integrity check—we would expect the code to conserve it under synonymous mutations. The fact that it does not suggests that any parity-like structure in the code is a byproduct of the chemical-grouping optimization, not a conserved feature in its own right.

### 4.3 Relation to Wobble Rules and Rumer Symmetry

The Crick wobble hypothesis [1] explains which third-position base pairs are tolerated by the ribosome. Our results are orthogonal: we are not concerned with which base pairs are physically possible, but with the parity consequences of the synonymous substitutions that the degeneracy pattern permits. The wobble rules determine which substitutions are synonymous; the Z-parity table then classifies the parity behavior of those synonymous substitutions.

Rumer [6] observed a complementarity symmetry in the codon table: exchanging each nucleotide with its complement (A↔T, G↔C) maps degenerate codons to non-degenerate ones and vice versa. Our Z-parity is a different invariant—it is defined by a 2-bit XOR, not by Watson–Crick complementarity—but both capture aspects of the codon table's binary structure. The key distinction is that Rumer symmetry is a property of the table itself, while Z-parity conservation is a *dynamical* question about what happens under mutation.

## 5 Formal Verification

All results are formalized in Lean 4 (version 4.27.0) using the Mathlib library. The five principal modules are:

- `ZInvariantPipeline.lean`: nucleotide encoding, codon Z-parity definition.
- `AminoAcidZClassification.lean`: amino acid chemical properties, degeneracy classes, chemical distance.
- `ZParityDegeneracyTable.lean`: exhaustive parity profiles for all 20 amino acids (Table 1).
- `WobbleZParity.lean`: wobble pairs, the parity-flip theorem, and the mixed-behavior existence proof.
- `ConservationHierarchy.lean`: the three hierarchy theorems and the combined summary.

Every theorem in this paper is verified by the Lean kernel via either `decide` or `native_decide`. The formalization contains zero axioms and zero `sorry` assertions.

## 6 Conclusion

The standard genetic code does not conserve Z-parity under synonymous wobble substitutions. Instead, a strict conservation hierarchy holds: amino-acid identity is the most strongly conserved quantity, followed by chemical similarity, with Z-parity as the weakest. This hierarchy is verified exhaustively for all 20 amino acid families and formalized in Lean 4.

The observation is small but structurally precise: it shows that the code's degeneracy budget is allocated to chemical error minimization rather than to the conservation of any binary codon-level invariant.
